## **Abstract**

The Gulf of Papua (GoP) is one of the best modern examples of low latitude mixed carbonate/siliciclastic system where the northern extremity of the Great Barrier Reef meets huge volumes of siliciclastics dumped by the Fly and other PNG rivers. Results of studies, focusing on the GoP shelf edges and adjacent upper slopes, demonstrate a clear switch from thick prograding muddy early sea level fall siliciclastic wedges and lowstand shelf edge deltas to transgressive growth of healthy coralgall edifices.

In Ashmore Trough, a proximal slope basin adjacent to the southern GoP shelf edge, a siliciclastic mud unit, well imaged in 3.5 kHz profiles as a distinctive semi-transparent homogeneous 18 to 50 m-thick package, was deposited during an early sea level fall interval. Based upon 3.5 kHz profiles, industry seismic lines, and one piston core, the shelf edge itself consists also of partially eroded siliciclastic prograding lowstand shelf edge deltas and coastal sediment accumulation.

Along the southwestern GoP shelf edge, the surveys uncovered a 30 to 50 m-high ridge that parallels the shelf edge with linear segments exceeding 10 km in length. Analyses of a core, recovered in a re-entrant in front of the ridge, demonstrate that a coastline, essentially siliciclastic, reached the present-day shelf break during Last Glacial Maximum - LGM (23 cal. Ka) and the Oldest Dryas - OD (17.5-16.5 cal. ka). During a major pulse of sea level rise, between ~ 15.0 and 13.0 cal. ka, a coralgall reef established itself on top

of a LGM/OD siliciclastic beach barrier complex, and subsequently drowned. On the northwest PNG shelf edge, an early transgressive, as thick as 80 m, corallgal edifice complex, established itself on top of a LGM shelf edge delta lobe. A piston core sampled the flank of one of the corallgal edifices and recovered a coral colony in growth position at ~ 107 m below modern sea level and dated at 19 cal. Ka.

The siliciclastic/carbonate switch observed during the last glacial sea level cycle in the GoP was repeated several times during the last 4 My. On seismic lines provided by Fugro/Finder Exploration Ltd, high-amplitude mounded seismic facies are overlying a series of prograding transparent/low amplitude wedges. These features are interpreted, as in the late Quaternary, to represent early transgressive shelf edge carbonate edifices, established and growing on top of siliciclastic muddy wedges deposited during intervals of forced regressions.

Maximum Lowstand (Last Glacial Maximum) ~30 to 16 ka

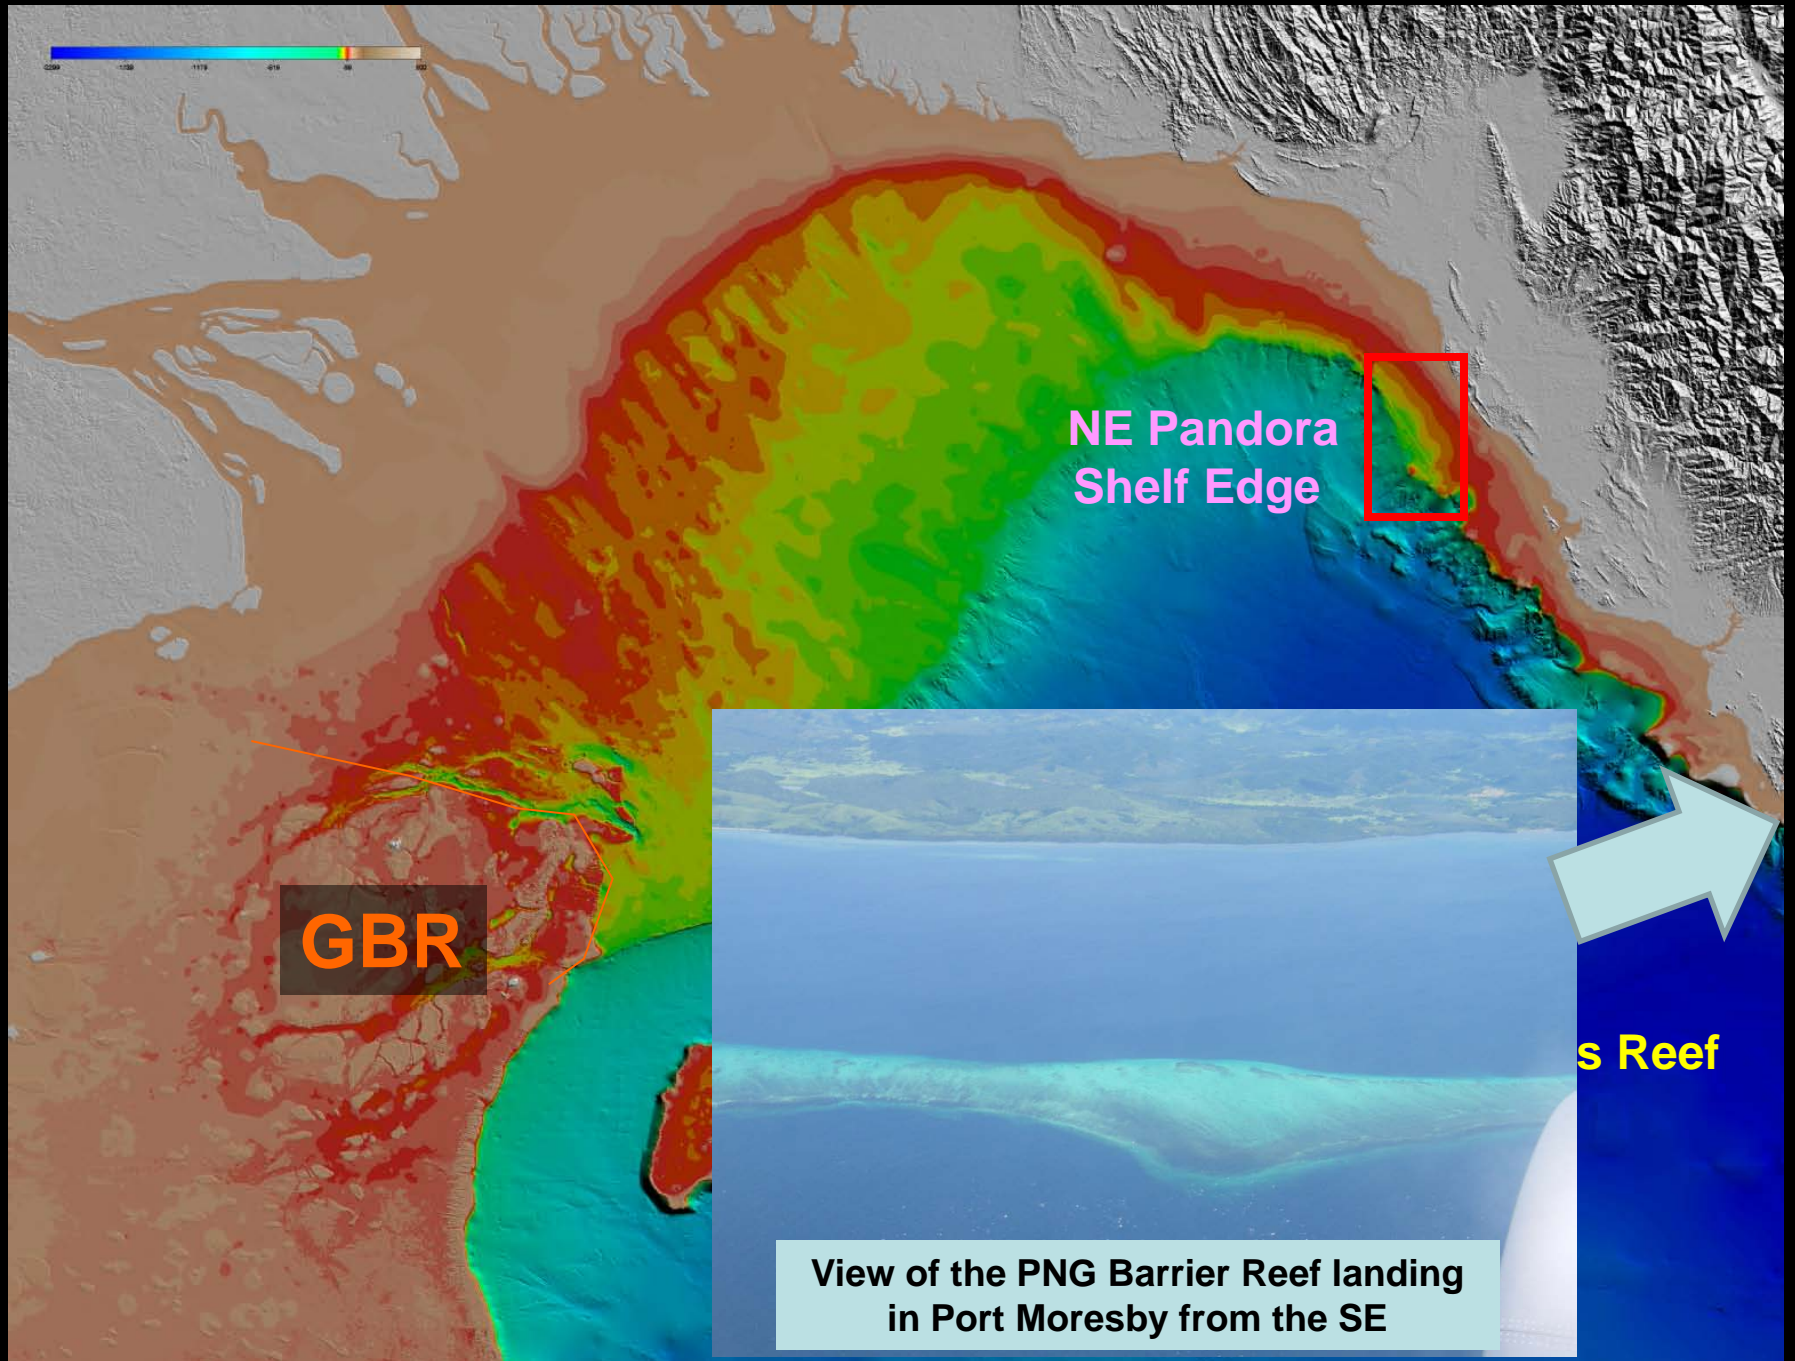

A ridge (drowned barrier reef) as high as 50 m and as long as ~ 50 km

**Several drowned coralgall reefs  
are observed along the edges of  
the GoP low latitude  
siliciclastic continental shelf.**

**Responding to  
the initial sea level rise,  
these coralgall reefs  
established themselves on top of  
former lowstand siliciclastic  
coastal deposits  
(siliciclastic beach ridges/deltas)  
once the new coast line  
had migrated further towards land.**

**These transgressive corallgal reefs  
first thrived during the early part of  
the last deglaciation  
by growing vertically  
as much as 50 to 70 m,  
but finally drowned  
not being capable to  
continuously keep up  
with the rise of sea level.**

# Buried Earlier Transgressive Barrier Reefs on top of lowstand shelfedge delta

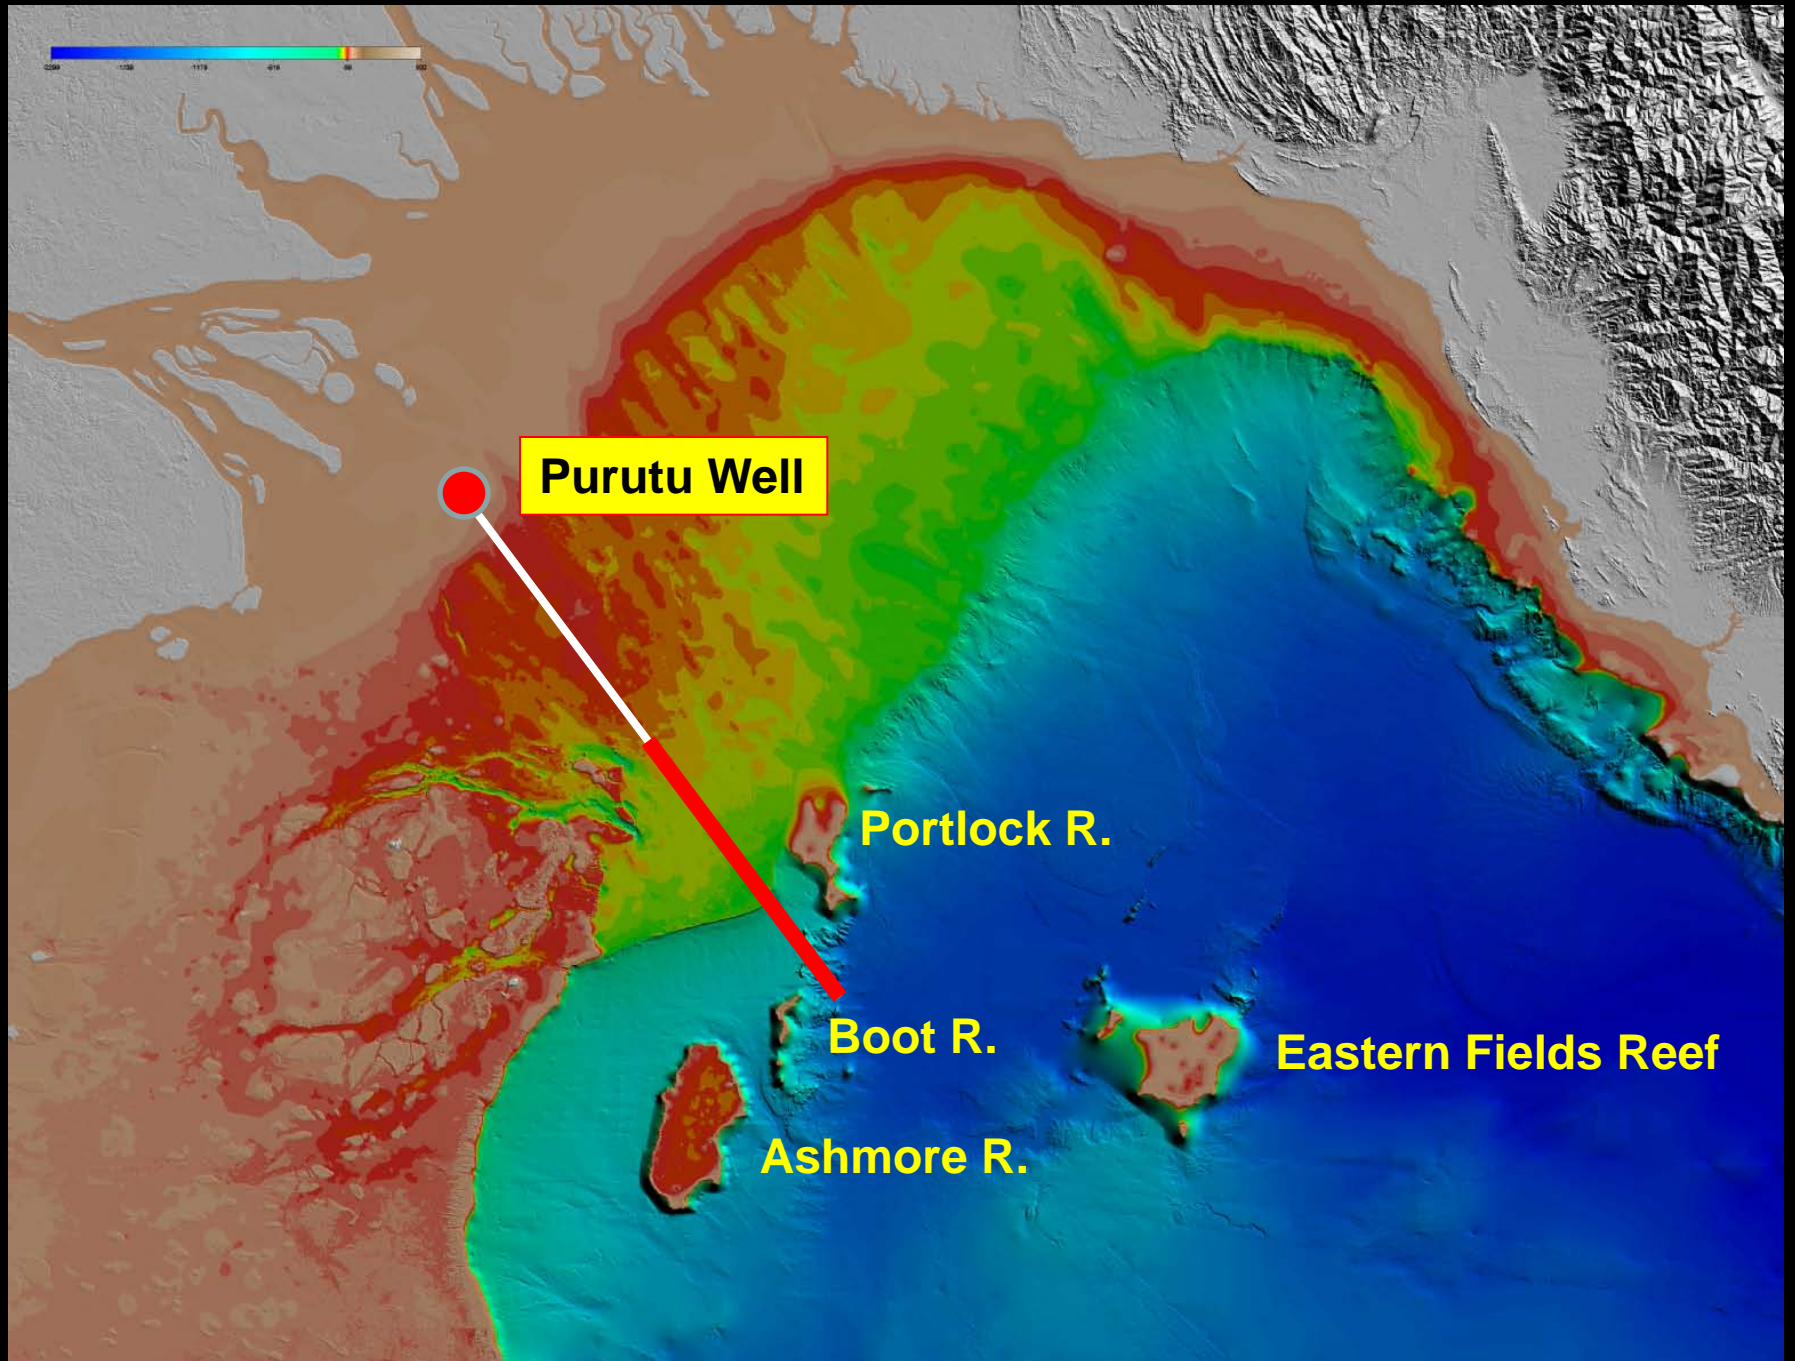

**This simple scenario for coralgall reef establishment and growth during the last early sea level transgression subsequent to the last Glacial Maximum sea level lowstand, was apparently repeated in the Quaternary during intervals marked by major transgressions.**

**In the Quaternary, at least three major sea level transgressions (~ 400-500 ky) terminated long intervals of significant sea level fall and lowstand,**

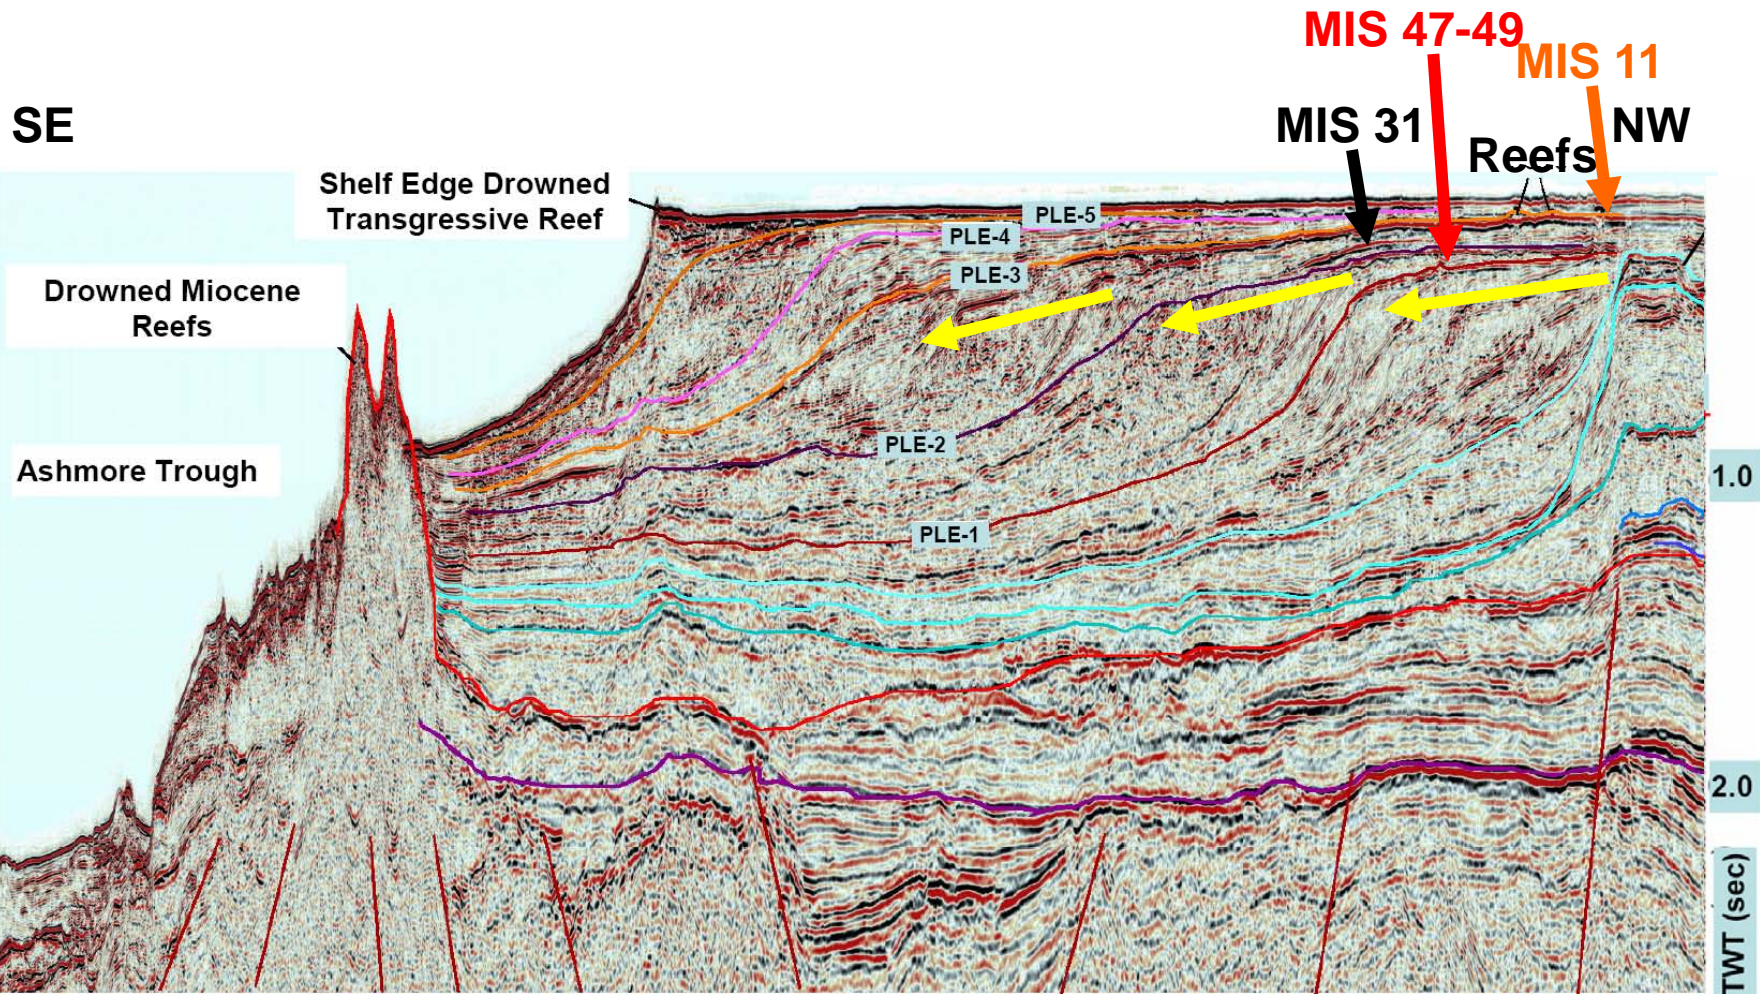

- 1) during the Mid-Brunhes (Marine Isotope Stage MIS 12 to 11, about 450 ka; i.e. Great Barrier Reef, Florida Keys, Belize and New Caledonia),**
- 2) during two other transgressive intervals at about 1.0 and 1.5 Ma (MIS 34 to 31 and MIS 52 to 47, respectively; observed in the Gulf of Papua.**

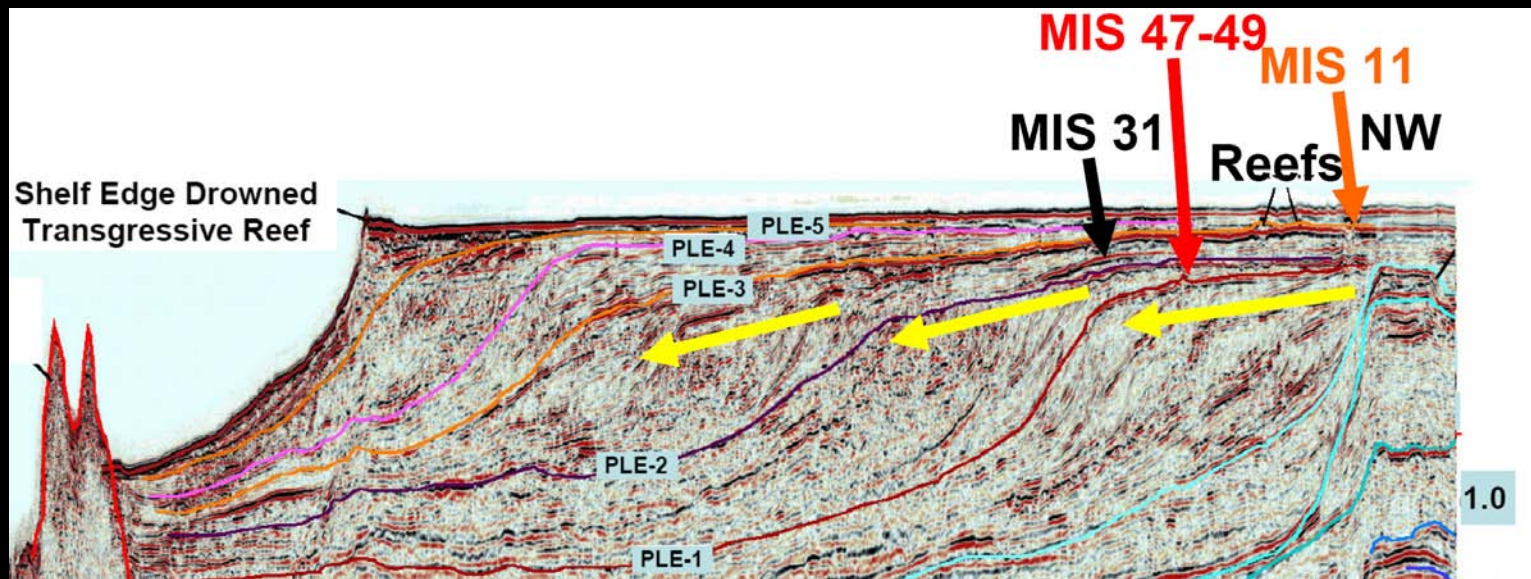

Fugro Multi Clients Services

**Purutu Well**

**During the late Pliocene,  
several ephemeral, but well-developed,  
phases of neritic carbonate growth  
are observed on the edges of  
the Gulf of Papua siliciclastic shelf,  
at the times when shelf edges  
were simultaneously prograding and  
aggrading (relative sea level  
transgressions).**

**The best developed late Pliocene  
neritic carbonate edifices  
on top of shelf edge  
siliciclastic sediments  
in the Gulf of Papua  
have occurred during  
the transgressions leading to  
the "mid-Pliocene warm interval"  
(~3.1 to 2.8 Ma).**
